Received 18 June 2008; published 3 November 2008

We report the first observation of $Y(2S) \rightarrow \eta Y(1S)$, with a branching fraction $B = (2.1^{+0.6}_{-0.7}\text{(stat)} \pm 0.3\text{(syst)}) \times 10^{-4}$ and a statistical significance 5.3$\sigma$. Data were acquired with the CLEO III detector at the CESR $e^+e^-$ symmetric collider. This is the first process observed involving a $b$-quark spin flip. For related transitions, 90% confidence limits in units of $10^{-5}$ are $B(Y(2S) \rightarrow \pi^0 Y(1S)) < 1.8$, $B(Y(3S) \rightarrow \eta Y(1S)) < 1.8$, $B(Y(3S) \rightarrow \pi^0 Y(1S)) < 0.7$, and $B(Y(3S) \rightarrow \pi^0 Y(2S)) < 5.1$.

In order to produce a pseudoscalar meson $\eta$ or $\pi^0$ in $Y(nS) \rightarrow (\eta/\pi^0) Y(1S)$ transitions, the $b\bar{b}$ pair must emit either two $M1$ (chromomagnetic dipole) gluons or an $E1$ (chromoelectric dipole) and an $M2$ (chromomagnetic quadrupole) gluon [1–3], involving the flip of a heavy quark’s spin. In this Letter we present the first observation of $Y(2S) \rightarrow \eta Y(1S)$, and a search for similar $\pi^0$ or $\eta$ transitions from the $Y(2S)$ and $Y(3S)$. A spin flip of a $b$-quark can shed light on its chromomagnetic moment, expected to scale as $1/m_b$. Electromagnetic transitions involving a $b$-quark spin flip should also have amplitudes scaling as $1/m_b$. They have not previously been observed.
The decay $\psi(2S) \rightarrow \eta J/\psi$ was observed in the early
days of charmonium spectroscopy [4]. Its branching fraction
is $\mathcal{B}(\psi(2S) \rightarrow \eta J/\psi) = (3.13 \pm 0.08\%)$ [5],
while only an upper limit $\mathcal{B} < 2 \times 10^{-3}$ is known for the corre-
sponding $Y(2S) \rightarrow \eta Y(1S)$ process [6]. The upper limit
for $Y(3S) \rightarrow \eta Y(1S)$ is $\mathcal{B} < 2.2 \times 10^{-3}$ [7]. The quark
spin-flip involved in $Y(nS) \rightarrow (\eta/\pi^0) Y(mS)$ transitions
(we consider $3 \leq n > m \geq 1$) and the $P$-wave nature of the final
state imply that rates should scale from charmonium as $\Gamma \propto (p^*)^3/m_0^3$ [1,2], where $p^*$ is the three-
momentum of the $\eta$ or $\pi^0$ in the $Y(nS)$ center-of-mass
system and $Q = c, b$ is the heavy quark. Hence one expects
\begin{equation}
\frac{\Gamma(Y(2S, 3S) \rightarrow \eta Y(1S))}{\Gamma(\psi(2S) \rightarrow \eta J/\psi)} = (0.0025, 0.0013),
\end{equation}
leading to $\mathcal{B}(Y(2S, 3S) \rightarrow \eta Y(1S)) \approx (8.0, 6.5) \times 10^{-4}$. Direct
calculation in a potential model [2] yields $(6.9, 5.4) \times 10^{-4}$ for these branching fractions. All predictions
involve a perturbative calculation of gluon-pair emission
followed by a nonperturbative estimate of materialization of the gluon pair into an $\eta$. Uncertainties
associated with this estimate are difficult to quantify.

Similar predictions can be made for $\pi^0$ transitions under
the assumption that they are due to an isospin-zero admix-
ture in the $\pi^0$. The isospin-forbidden decay $\psi(2S) \rightarrow
\pi^0 J/\psi$ has been seen [5] with a branching fraction of
$(1.26 \pm 0.13) \times 10^{-3}$ which is $(4.03 \pm 0.43\%)$ of that for
$\psi(2S) \rightarrow \eta J/\psi$. Using values of $p^*$ appropriate to each
process and assuming the same isospin-zero admixture in $\pi^0$
permits the transitions $Y(nS) \rightarrow \pi^0 Y(mS)$, one obtains the scaling predictions
\begin{equation}
\frac{\mathcal{B}(Y(2S, 3S) \rightarrow \pi^0 Y(1S))}{\mathcal{B}(Y(2S, 3S) \rightarrow \eta Y(1S))} = (16 \pm 2, 0.42 \pm 0.04\%).
\end{equation}
There is no prediction at present for the kinematically-
allowed decay $Y(3S) \rightarrow \pi^0 Y(2S)$.

The data in the present analysis were collected in $e^+e^-$
collisions at the Cornell Electron Storage Ring (CESR),
at center-of-mass energies at and about 30 MeV below the
$Y(2S, 3S)$ resonances. Integrated luminosities at these
resonances were $(1.3, 1.4)$ fb$^{-1}$, amounting to $(9.32 \pm
0.14, 5.88 \pm 0.10)$ million decays of $Y(2S, 3S)$, as in the
analysis of Ref. [8]. Events were recorded in the CLEO III
detector, equipped with an electromagnetic calorimeter
consisting of 7784 CsI(Tl) crystals and covering 93% of
solid angle, initially installed in the CLEO II [9] detector
configuration. The energy resolution of the crystal calor-
imeter is 5% (2.2%) for 0.1 (1) GeV photons. The CLEO
III tracking system [10] consists of a silicon strip detector
and a large drift chamber, achieving a charged particle
momentum resolution of 0.35% (1%) at 1(5) GeV/c in a
1.5 T axial magnetic field.

We look for candidate events of the form $e^+e^- \rightarrow
Y(nS) \rightarrow (\eta/\pi^0) Y(mS)$ with $Y(mS) \rightarrow \ell^+ \ell^-$, where $\ell = e, \mu$. Candidates for $\ell^\pm$
are identified by picking the two
highest-momentum tracks in an event and demanding them
to be of opposite sign. We explore separate $e^+e^-$ and $\mu^+\mu^-$ samples in $Y(mS)$ decays by defining electron
candidates to have a high ratio of energy $E$ observed in the
calorimeter to momentum $p$ measured in the tracking
system, i.e., $E/p > 0.75$, and muon candidates to have $E/p < 0.20$. We choose lepton candidates from tracks
satisfying $|\cos \theta| < 0.83$, where $\theta$ is the angle with respect
to the positron beam direction, to avoid a region of less
uniform acceptance at larger $|\cos \theta|$. With these criteria we
achieve a very clean separation of electron and muon
candidates. In order to suppress contributions from
Bhabha scattering, we demand for events with $(\eta, \pi^0) \rightarrow
\gamma \gamma$ that $e^+$ candidates satisfy $|\cos \theta_{e^+} < 0.5$. This greatly
suppresses Bhabha scattering background while keeping
93% of the signal. Once leptons are identified, the
entire event is kinematically fitted. We reconstruct the $\eta$
candidates from their decays to $\gamma \gamma, \pi^+ \pi^- \pi^\pm$, and $3\pi^0$.
We did not employ the decay mode $\eta \rightarrow \pi^+ \pi^- \pi^0$ be-
because of its small branching fraction $(\mathcal{B} = [4.69 \pm
0.10]%)$ [5]) and large backgrounds, primarily from
$Y(nS) \rightarrow \pi^+ \pi^- Y(mS)$.

Photon candidates must be detected in the central region
of the calorimeter ($|\cos \theta| < 0.81$), must not be aligned
with the initial momentum of a track, and should have a
lateral shower profile consistent with that of a photon.
Neutral pion candidates (except in the decay $\eta \rightarrow 3\pi^0$,
where we only look for six photon candidates) are recon-
structed from a pair of $\gamma$ candidates required to have $\gamma \gamma$
invariant mass between 120 and 150 MeV.

Monte Carlo (MC) samples were generated for generic
$Y(2S, 3S)$ decays using the routine QQ [11], and for
$Y(nS) \rightarrow (\eta/\pi^0) Y(mS)$ and dipion transitions between
$Y$ states using the package EVTGEN [12]. The final
$Y(mS)$ state was taken to decay to $e^+e^-$ or $\mu^+\mu^-$. A
GEANT-based [13] detector simulation was used. These
samples, as well as off-resonance $Y(2S)$ data, are useful
both for validating background suppression methods and as
possible background sources. In calculating branching
fractions from data, we take $\mathcal{B}(Y(1S) \rightarrow e^+e^-) =
\mathcal{B}(Y(1S) \rightarrow \mu^+\mu^-) = 0.0248 \pm 0.0005$ [5] and
$\mathcal{B}(Y(2S) \rightarrow e^+e^-) = \mathcal{B}(Y(2S) \rightarrow \mu^+\mu^-) = 0.0203 \pm
0.0009$ [14] based on the more accurately measured $\mu^+\mu^-$
branching fractions and assuming lepton universality.

The $Y(nS) \rightarrow (\eta/\pi^0) Y(mS)$ MC samples were generated
with $\eta$ and $\pi^0$ decaying through all known decay
modes. These decays proceed via a $P$ wave, and hence are
described by a matrix element $(e_i \times \epsilon_f^*) \cdot P(q/\pi^0)$ in the
nonrelativistic limit (here $\epsilon_i$ denotes complex conjugation),
with $e_i, \epsilon_f$ the polarization vectors of the final and initial $Y$.
The $\theta$ distribution for the final-state leptons in $Y(mS) \rightarrow
\ell^+ \ell^-$ then is $1 - (1/3) \cos^2 \theta$, and was used in all signal
MC samples for $Y(nS) \rightarrow (\eta/\pi^0) Y(mS)$. For $Y(nS) \rightarrow
\pi^+ \pi^- Y(mS)$ it was assumed that the $Y(mS)$ retains the
polarization of the initial $Y(nS)$, so the lepton angular
distribution for $Y(mS) \rightarrow \ell^+ \ell^-$ is $1 + \cos^2 \theta$. 

192001-2
As a cross-check, data were analyzed for the known transitions $Y(nS) \rightarrow \pi \pi' Y(1S)$, and branching fractions were found in sufficiently good agreement with world averages [5]. We looked for systematic differences between detection of $Y(1S) \rightarrow e^+ e^-$ and $Y(1S) \rightarrow \mu^+ \mu^-$. Efficiencies for the two modes can differ as a result of the requirement on $\cos \theta_{e^-}$ mentioned above. The branching fractions calculated from $Y(1S) \rightarrow e^+ e^-$ and $Y(1S) \rightarrow \mu^+ \mu^-$ were found to be equal within statistical uncertainty, and consistent with those obtained from recoil mass spectra without requiring final leptons.

Kinematic fitting was used to study the decays $Y(nS) \rightarrow (\gamma/\pi^0)Y(mS)$. The two tracks selected as leptons, including photon bremsstrahlung candidates within 100 mrad of the initial lepton direction, were constrained to have the known masses of $Y(mS)$ with a resultant reduced $\chi^2$ ($\chi^2$/d.o.f.), $\chi^2 = \chi^2_{EVT,m}$ required to be less than 10. (For off-resonance data the dilepton masses were reduced by an amount equal to the initial $M[Y(nS)]$ minus the off-resonance center-of-mass energy.) The sum of the four-momenta of these two fitted tracks, including photon bremsstrahlung candidates as well as the decay products of the $\gamma/\pi^0$, were further constrained to the initial $Y(nS)$ four-momentum, with a reduced $\chi^2 = \chi^2_{EVT,m}$ required to be less than 10, or 30 for $(\gamma/\pi^0) \rightarrow \gamma \gamma$ to help suppress doubly radiative Bhabha events. Some of these Bhabha events can give small fitted $\chi^2_{EVT,m}$, but have photon momenta shifted by relatively large amounts compared to signal events. To further suppress such events, two-photon “pull” masses, defined as ((fitted − measured)/$\sigma$, where $\sigma$ is the two-photon mass resolution, were chosen on the basis of signal MC and off-resonance data (containing the doubly radiative Bhabha contribution) to lie between $\pm 2$ and 3. Over 99% of the signal MC events for all transitions satisfy this criterion. All particles were also required to have common vertices in the above two constrained fits, with reduced $\chi^2 < 30$ for the dilepton vertex, and reduced $\chi^2_{EVT,v} < 30$ required for the full event vertex.

For $Y(2S) \rightarrow \eta Y(1S)$, the photons from $\eta \rightarrow \gamma \gamma$ have energies $E_{\gamma} = (281 - 64 \cos \theta^*)$ MeV, where $\theta^*$ is the angle between the photon in the $\eta$ center-of-mass and the $\eta$ boost, so $217 \leq E_{\gamma} \leq 345$ MeV. Choosing $200 \leq E_{\gamma} \leq 360$ MeV then eliminates background from $Y(2S) \rightarrow \gamma E_{\gamma} \rightarrow \gamma \gamma Y(1S)$ with little effect on the $\eta \rightarrow \gamma \gamma$ signal. Using the $Y(2S) \rightarrow \eta Y(1S)$ MC sample, the $\eta$ candidate mass distribution was fitted to the sum of a double Gaussian and a linear background. Constant background gave a worse fit because of the kinematic limit at $M[Y(2S)] - M[Y(1S)] = 563$ MeV. The fitting range was chosen to be 533 to 563 MeV: roughly symmetric about the $\eta$ peak ($M(\eta) = 547.51 \pm 0.18$ MeV [5]) with upper boundary at $M[Y(2S)] - M[Y(1S)]$ above which few events are expected or observed. The difference between fits with linear and flat backgrounds was found to be insignificantly different compared with the systematic error associated with fitting range. The double-Gaussian parameters included a narrow width $\sigma_1 = 0.9$ MeV, a wide width $\sigma_2 = 2.1$ MeV, area of second peak 20% of total, and mean of second peak 0.14 MeV below the first.

The mass distribution for the sum of the $\eta$ modes $\gamma\gamma$, $\pi^+\pi^-\pi^0$, and $3\pi^0$ in data (upper plot, Fig. 1) shows a clear peak near $M(\eta)$. We fit data points to the sum of the double Gaussian with floating area but fixed shape obtained from signal MC and a linear background. The $\pi^+\pi^-\pi^0$ and $3\pi^0$ decay modes each contribute two events near the peak and none elsewhere. The combined fitted peak corresponds to a branching fraction $\mathcal{B}(Y(2S) \rightarrow \eta Y(1S)) = (2.1^{+0.7}_{-0.6}) \times 10^{-4}$. Defining the significance $N_\sigma$ as $\sqrt{-2\Delta \log \mathcal{L}}$, where $\mathcal{L}$ is the likelihood, the difference between fits with and without signal yields a statistical significance of 5.3 standard deviations.

In searching for $Y(3S) \rightarrow \eta(\rightarrow \gamma\gamma) Y(1S)$ transitions, we suppress backgrounds from cascades involving intermediate $\chi_b(1P, 2P)$ states by requiring one photon to have $500 \leq E_1 \leq 725$ MeV and the other to have $140 \leq E_2 \leq 380$ MeV. Signal photons satisfy $E_{\gamma} = (435 - 350 \cos \theta^*)$ MeV, so about 2/3 of them are retained by these choices. Small differences with respect to $Y(2S) \rightarrow \eta Y(1S)$ include (a) an $\eta$ fit range 523–573 MeV and (b) a background limit (dashed line). In the bottom figure the solid curve corresponds to a best fit with signal MC shape, while the dotted curve corresponds to a 90% confidence level (C.L.) upper limit.
(b) a flat background, found here to be sufficient to describe MC calculations and data. The best fit to signal MC shape and the 90% confidence level (C.L.) upper limit are shown in the lower plot of Fig. 1. (No events were observed in the regions included in the fit but not shown in Fig. 1.)

For $Y(2S) \rightarrow \pi^0 Y(1S)$, the photons from $\pi^0 \rightarrow \gamma \gamma$ have energies $E_\gamma = (274 - 266 \cos \theta^\ast)$ MeV, so $8 \leq E_\gamma \leq 540$ MeV. The choice $200 \leq E_\gamma \leq 360$ MeV for both photons, made to eliminate background from $Y(2S) \rightarrow \gamma \gamma Y(1S)$, then retains about 30% of the $\pi^0 \rightarrow \gamma \gamma$ signal. A fit of the $M(\gamma \gamma)$ distribution in the data (using the signal MC double-Gaussian shape and uniform background) is shown in the top plot of Fig. 2. Details of this and other limits, as well as of the $Y(2S) \rightarrow \eta Y(1S)$ signal, are shown in Table I. For all $\pi^0$ transitions, MC simulations indicate a constant function is adequate to describe the background. Efficiency differences between decay modes are typically due to details of photon acceptance.

For $Y(3S) \rightarrow \pi^0 Y(1S)$, where signal photons from $\pi^0 \rightarrow \gamma \gamma$ satisfy $E_\gamma = (429 - 385 \cos \theta^\ast)$ MeV, the same ranges of $(E_1, E_2)$ are chosen as for $Y(3S) \rightarrow \eta Y(1S)$. For $Y(3S) \rightarrow \pi^0 Y(2S)$, we suppress backgrounds from cascades involving intermediate $\chi_3(2P)$ states by excluding photons with $60 \leq E_2 \leq 130$ MeV and $190 \leq E_1 \leq 260$ MeV. Here, the signal photons satisfy $E_\gamma = (164 - 149 \cos \theta^\ast)$MeV, so about 40% are retained. No signal is seen in any of these $\pi^0$ transitions (Fig. 2).

![FIG. 2 (color online). Best fits to two-photon invariant mass distributions with signal MC shapes (solid curves are the results of total fits) and 90% C.L. upper limits (dotted curves) for $Y(2S) \rightarrow \pi^0 Y(1S)$ (top), $Y(3S) \rightarrow \pi^0 Y(1S)$ (middle), and $Y(3S) \rightarrow \pi^0 Y(2S)$ (bottom).](image-url)
Kinematic fitting: To probe any systematic bias introduced by our kinematic fitting procedure, we look at events with very similar topology to our signals: $Y(2S) \rightarrow \gamma \chi_b(1P_J)$, $\chi_b(1P_J) \rightarrow \gamma Y(1S)$, $Y(1S) \rightarrow \ell^+ \ell^-$ where $J = 1$ or 2. We use the same analysis requirements as for $\eta \rightarrow \gamma \gamma$ but relax the requirements on $E_\gamma$ in order to accept two-photon cascades through $\chi_b$ states. Varying the requirement on $X^2_{\text{EVT,m}}$ from none to $X^2_{\text{EVT,m}} < 3$, we observe a maximum deviation of 7% in this product of branching fractions which we assign as a possible source of systematic uncertainty. (iii) $\eta/\pi^0$ reconstruction: We assign 5% per $\pi^0$ or $\eta$ decaying into two photons based on CLEO studies [15]. (iv) Fit ranges: Uncertainties due to fit ranges differ for different final states. To estimate them, we prepare many MC samples in which points are randomly scattered around best-fit values from data (signal plus background), bin-by-bin according to a Poisson distribution. We then fit them with the fit range boundaries symmetrically changed by $\pm 5$ MeV for $Y(2S) \rightarrow \eta Y(1S)$. In $Y(3S) \rightarrow \eta Y(1S)$ as well as in $Y(nS) \rightarrow \pi^0 Y(mS)$, where wider kinematic ranges are available, the fit range boundaries are symmetrically changed by $\pm 10$ MeV. We assign variations of averages of these fitted yields as possible systematic shifts. Combining the effects from the systematic errors linearly with the results already listed, we find the results shown in the last line of Table II.

To summarize, we have observed for the first time a $\pi^0 Y(1S)$ transition. The result is about $1/4$ of the value one would predict on the basis of Eq. (1), indicating either a shortcoming in the description of two-gluon hadronization into an $\eta$ or a fundamental suppression of the chromomagnetic moment of the $b$ quark. In addition, we have set 90% C.L. upper limits on other pseudoscalar transitions summarized on the bottom line of Table II. The limit on $B(Y(3S) \rightarrow \eta Y(1S))$ is about a factor of 2 below that predicted from Eq. (1), while the limits on the transitions $Y(2S, 3S) \rightarrow \pi^0 Y(1S)$ are consistent with the estimates of Eq. (2).

We gratefully acknowledge the effort of the CESR staff in providing us with excellent luminosity and running conditions. This work was supported by the A.P. Sloan Foundation, the National Science Foundation, the U.S. Department of Energy, the Natural Sciences and Engineering Research Council of Canada, and the U.K. Science and Technology Facilities Council.
