Bayesian learning in assisted brain-computer interface tasks

Yin Zhang\(^1\), Andrew B. Schwartz\(^2\), Steve M. Chase\(^1\) and Robert E. Kass\(^1\)

Abstract—Successful implementation of a brain-computer interface depends critically on the subject’s ability to learn how to modulate the neurons controlling the device. However, the subject’s learning process is probably the least understood aspect of the control loop. How should training be adjusted to facilitate dexterous control of a prosthetic device? An effective training schedule should manipulate the difficulty of the task to provide enough information to guide improvement without overwhelming the subject. In this paper, we introduce a Bayesian framework for modeling the closed-loop BCI learning process that treats the subject as a bandwidth-limited communication channel. We then develop an adaptive algorithm to find the optimal difficulty-schedule for performance improvement. Simulation results demonstrate that our algorithm yields faster improvement in learning rate. Here we introduce a Bayesian framework for modeling a closed-loop BCI learning process that incorporates shared-mode control. By treating the subject as a bandwidth-limited communication channel, we demonstrate an explicit link between the difficulty-schedule and the learning rate. We then develop an adaptive algorithm to find the optimal difficulty schedule for performance improvement. In simulation, our adaptive difficulty-control strategy promotes a marked improvement in learning rate.

I. INTRODUCTION

Brain-computer interfaces (BCI) promise to restore movement to those who are paralyzed by providing behavioral output directly from the intention to move, bypassing defective neural transmission and muscle activation [3], [5], [7]. However, the control algorithms currently used in BCI are far from perfect: successful decoding still depends critically on the subject’s ability to learn how to produce the appropriate neural activity patterns. In closed-loop control, poor estimates of intention can potentially be corrected on-line by the subject. However, to know the appropriate corrective action, the subject has to already have some facility at control. If the subject has no understanding of the mapping between neural activity and effector movement, even the corrective movement will be wrong. To facilitate this learning process, computer assistance is often used at the beginning stages of training to minimize the errors that the subject makes while learning the task [6], [7]. In shared-mode control (SMC), the subject’s volitional signal is mixed with a computer-generated “correct” signal to generate the final output. By limiting the errors that the subject produces, SMC increases motivation and keeps the subject engaged in the learning process.

SMC provides a means of directly manipulating the difficulty of the task. How should this difficulty-schedule be chosen? If the difficulty is too low, the errors will be artificially small and the subject will have no pressure to learn. If the difficulty is too high, the errors will be too large to be meaningfully interpreted. The task difficulty must be carefully titrated to the subject’s ability to promote rapid learning. Here we introduce a Bayesian framework for modeling a closed-loop BCI learning process that incorporates shared-mode control. By treating the subject as a bandwidth-limited communication channel, we demonstrate an explicit link between the difficulty-schedule and the learning rate. We then develop an adaptive algorithm to find the optimal difficulty schedule for performance improvement. In simulation, our adaptive difficulty-control strategy promotes a marked improvement in learning rate.

II. THE TASK

In this paper we consider the center-out reaching task. In this task, starting from the centered home position, the subject needs to control a cursor on a surface to reach a target at position \( \tau \). The subject’s activity is denoted as \( \phi \) and the corresponding cursor’s movement direction is denoted as \( \psi \). For simplicity, \( \phi \) is also treated as an angle in this paper. For more complex activity, it can first be projected onto the 1D space. The control system’s mapping function \( f \) is a rotation with an angle \( \theta^* \), i.e.,

\[
\psi = f(\phi; \theta^*) = \phi + \theta^*
\]

where \( \theta^* \) is the system’s parameter and is hidden from the subject. Therefore, the subject’s learning process is essentially a system identification process because in order to get the desired output (the cursor’s ideal movement) the subject needs to find \( \theta^* \) throughout a series of observations about the system’s inputs and outputs.

The routine of the subject’s knowledge updating at \( t \)-th step is shown in Fig. 1 and the notations are shown in Table I. The cursor’s desired movement direction \( \psi^*_t \) is determined by the cursor’s current position \( s_t \) and the target’s position. The subject’s guess about the system parameter, \( \theta_{t-1} \), is generated from the subject’s current knowledge about \( \theta^* \). Together with \( \psi^*_t \), the subject can figure out the desired input \( \phi_t^* \) as

\[
\phi_t^* = f^{-1}(\psi_t^*; \theta_{t-1}) = \psi_t^* - \theta_{t-1}
\]

Correspondingly, the subject’s intended output without any assistance is \( f(\phi_t^*; \theta^*) \). However, under SMC, the cursor’s actual movement direction is the subject’s intended output corrected by a factor \( \lambda_t \), which is equivalent to the linear combination of the subject’s intended output \( f(\phi_t^*; \theta^*) \) and the desired output \( \psi^*_t \), i.e.,

\[
\psi_t = \lambda_t f(\phi_t^*; \theta^*) + (1 - \lambda_t) \psi_t^*
\]

When \( \lambda_t = 1 \), we have \( \psi_t = f(\phi_t^*; \theta^*) \) which means there is no assistance at all and the subject fully controls the cursor’s movement. When \( \lambda_t = 0 \), we have \( \psi_t = \psi_t^* \) which means the

![Fig. 1](Image of one-step updating)

The cursor will always move in the ideal direction. Therefore, $\lambda_t$ reflects the difficulty of the task and our purpose is to adjust $\lambda_t$ adaptively to facilitate the subject’s learning. After the $t$-th step, the cursor moves to a new position $s_{t+1}$ determined by $s_t$ and $\psi_t$.

The system’s input-output pair $\{\varphi_t, \psi_t\}$ provides some new information about the system and the subject updates the knowledge based on the perception about the input-output pair, denoted as $\{\varphi_t, \hat{\psi}_t\}$. Here we argue that the subject’s perception about the cursor’s movement direction, $\hat{\psi}_t$, is a noisy version of $\psi_t$, i.e.,

$$\hat{\psi}_t = \psi_t + \epsilon_{\psi_t}$$  \hspace{1cm} (4)

where $\epsilon_{\psi_t}$ is zero-mean Gaussian noise with variance $\sigma_{\psi_t}^2$. We will discuss this noise term in detail in Section III-B.

### III. The Model

As we have discussed in the previous section, the learning process in our task is in fact a system identification process and in this paper, we proposed a Bayes learning framework to model this process. In our framework, the subject’s knowledge about $\theta^*$ is a random variable $\theta$ with probability density function $p(\theta)$. At the beginning of the learning task, $p(\theta)$ is fairly flat because the subject is quite uncertain about the system and as the training takes place, the distribution sharper around $\theta^*$.

For simplicity, the subject’s initial knowledge $p_0(\theta)$, which is the prior probability before any observations, is assumed as Gaussian distribution, i.e., $p_0(\theta) = \mathcal{N}(\mu_0, \sigma_0^2)$, where $\mu_0$ is an arbitrary guess and $\sigma_0^2$ is fairly large.

#### A. Bayes Learning

The subject’s knowledge about $\theta^*$ at the beginning of the $t$-th step, denoted as $p_{t-1}(\theta)$, is the posterior probability after observing the input-output sequence in the first $(t-1)$ steps,

$$p_{t-1}(\theta) = p(\theta | \varphi_j, \psi_{j-1})$$  \hspace{1cm} (5)

The subject’s guess about $\theta^*$, $\theta_{t-1}$, is sampled from $p_{t-1}(\theta)$, i.e., $\theta_{t-1} \sim p_{t-1}(\theta)$. At the end of the $t$-th step, the subject acquires some new information about $\theta^*$ from the perceived data $\{\varphi_t, \hat{\psi}_t\}$, and updates $p_{t-1}(\theta)$ by Bayes rule,

$$p_t(\theta) \propto p_{t-1}(\theta) p(\varphi_t, \hat{\psi}_t | \theta)$$  \hspace{1cm} (6)

To get the likelihood, we notice at the $t$-th step, the system’s input is $\varphi_t$ and the output is $\psi_t$ and $\theta$ is the subject’s conjecture about the system’s parameter. Thus,

$$\psi_t = \varphi_t + \theta$$  \hspace{1cm} (7)

and

$$\hat{\psi}_t = \psi_t + \epsilon_{\psi_t} = \varphi_t + \theta + \epsilon_{\psi_t}$$  \hspace{1cm} (8)

Since $p(\hat{\psi}_t, \varphi_t | \theta) = p(\psi_t | \varphi_t, \theta) p(\varphi_t | \theta)$ and $\varphi_t$ is independent of $\theta$, we have the likelihood as

$$p(\hat{\psi}_t, \varphi_t | \theta) \propto \mathcal{N}(\varphi_t + \theta, \sigma_{\psi_t}^2)$$  \hspace{1cm} (9)

#### B. Noise Term $\epsilon_{\psi_t}$

To get $\epsilon_{\psi_t}$ in this paper, we treat the subject as a communication channel with a limited bandwidth. Form Shannon-Hartley theorem we know that the channel capacity $C_{\text{max}}$, or, in our case, the upper bound on the information rate the subject can acquire each step is

$$C_{\text{max}} \geq C_t = B \log (1 + S_t/N_t)$$  \hspace{1cm} (10)

where $C_t$ is the information rate at the $t$-th step, $B$ is a constant related to the bandwidth of the channel, $S_t$ and $N_t$ are the powers of the signal and the noise at the $t$-th step.

To get $S_t$, we notice when the system’s input is $\varphi_t$, the subject’s expected cursor’s movement direction is $\psi_t^*$. Thus, the difference between the subject’s expected output and the actual output, i.e., the error, can be considered as the signal power, i.e.,

$$S_t = (\psi_t - \psi_t^*)^2$$  \hspace{1cm} (11)

The noise power comes from the noise term $\epsilon_{\psi_t}$. Since it is Gaussian noise, the noise power equals to its variance

$$N_t = \sigma_{\psi_t}^2$$  \hspace{1cm} (12)

Thus, we get the information rate at the $t$-th step as

$$C_t = B \log (1 + (\psi_t - \psi_t^*)^2/\sigma_{\psi_t}^2)$$  \hspace{1cm} (13)

In this paper, we assume the information rate can reach its upper bound, i.e., $C_t = C_{\text{max}}$, then, we have the expression of the noise’s variance as

$$\sigma_{\psi_t}^2 = \alpha (\psi_t - \psi_t^*)^2$$  \hspace{1cm} (14)

where $\alpha = \exp(C_{\text{max}}/B) - 1$ is a constant determined by the subject’s capability. Large $\alpha$ indicates the high capability of acquiring new information and vice versa. From Eq. 14, we can see the variance of the subject’s perception is proportional to the error. What’s more, notice the error can be expressed as

$$\psi_t - \psi_t^* = (\theta^* - \theta_{t-1})^2 \lambda_t^2$$  \hspace{1cm} (15)

Thus after the subject’s guess $\theta_{t-1}$ is generated, the error is solely determined by the task’s difficulty $\lambda_t$. This result reveals that when SMC is minimal ($\lambda_t = 1$), the subject...
receives veridical feedback about its movement, with the error that provide the most useful information for updating its internal conception of the motor transform. However, large error also leads to increased perceptual noise, \( \varepsilon_{\psi_t} \), limiting the subject's ability to utilize the feedback. This conclusion is similar to the statement in [2], where authors argued that there is a maximum volume of new information the subject can acquire each step. If the information provided by the task exceeds this threshold, more information will harm the subject's perception. [1] demonstrates the dependence of the degree of specificity on the task difficulty. This tension suggests that optimal learning may be driven by intermediate levels of assistance that decrease as the subject gains proficiency at the task. Finding the proper schedule of \( \lambda_t \) to optimize the rate of learning is the goal of this work.

C. Posterior Probability Updating

With the expression of likelihood, we can update the posterior probability, which is the subject's knowledge about \( \theta^* \) after the \( t \)-th step. Since \( p_0 \) is Gaussian and the likelihood at each step is also Gaussian, from induction we know \( p_t(\theta) \) is Gaussian. Assuming \( p_{t-1}(\theta) = N(\mu_{t-1}, \sigma_{t-1}^2) \), we have the updated posterior as \( p_t(\theta) = N(\mu_t, \sigma_t^2) \), where

\[
\begin{align*}
\mu_t &= \left( \mu_{t-1} - \sigma_{t-1}^2 + (\tilde{\psi}_t - \varphi_t)\sigma_{\psi_t}^{-2} \right) \sigma_t^2 \\
\sigma_t^2 &= \left( \sigma_{t-1}^2 + \sigma_{\psi_t}^{-2} \right)^{-1}
\end{align*}
\]  

(16)  

(17)

Some Observations: From the above equations, we can see the updated posterior mean is the linear combination of \( \mu_{t-1} \), which comes from the previous knowledge, and \( (\tilde{\psi}_t - \varphi_t) \), which comes from the new precieved data. From Section II, we can expand \( (\tilde{\psi}_t - \varphi_t) \) into two parts as

\[\tilde{\psi}_t - \varphi_t = (\lambda_t \theta^* + (1 - \lambda_t)\theta_{t-1}) + \varepsilon_{\psi_t}\]  

(18)

The first part \( (\lambda_t \theta^* + (1 - \lambda_t)\theta_{t-1}) \) reflects how much information about \( \theta^* \) the current step provides. When \( \lambda_t \) is close to 1, this part is close to \( \theta^* \), which means much information about the ground-truth parameter \( \theta^* \) is provided. On the other side, when \( \lambda_t \) is close to 0, this part is close to \( \theta_{t-1} \), which means the subject's observation is quite similar to what it has already learnt and little information about \( \theta^* \) is provided. So, from this point of view, to make the subject learn as much as possible, \( \lambda_t \) should be set as large as possible.

The second part \( \varepsilon_{\psi_t} \) is a random variable with variance \( \sigma_{\psi_t}^2 \). From the discussion in Section III-B we know when \( \lambda_t \) is large, with high probability \( \varepsilon_{\psi_t} \) is far away from 0. So, from this point of view, we want to keep \( \lambda_t \) small. Therefore, we hope to find a balance between those two parts.

IV. Adaptive Difficulty Control

In this section, we design a strategy which can automatically adjust the task's difficulty at each step so that the subject can learn as fast as possible. Specifically, when the system obtains the subject's input \( \varphi_t \), we hope the cursor can move in a proper direction that helps the subject improve its knowledge as much as possible.

To do this, we first define the risk of the subject's current knowledge as the mean squared error between \( \theta \) and \( \theta^* \), i.e.,

\[ R(p_t) = E_{p_t(\theta; \mu_t, \sigma_t)}(\theta - \theta^*)^2 = (\mu_t - \theta^*)^2 + \sigma_t^2 \]  

(19)

where \( (\mu_t - \theta^*)^2 \) is the bias, which measures the distance between the subject's knowledge and the ground-truth, and \( \sigma_t^2 \) is the variance, which measures the confidence about subject's knowledge.

To make the risk converge to 0 as fast as possible, one heuristic way is to minimize the expected risk of the next step, i.e.,

\[ \lambda_t = \arg \min_{\lambda} E_{\psi_t} \left[ R(p_t) \right] \]  

(20)

where \( p_t \) is given by Eq. 16.

However, from the simulation results (Fig. 4) we find this intuitive method doesn't work very well. It is because at the first few steps, the optimal \( \lambda \) minimizing Eq. 20 focuses on decreasing the variance of the risk while keeping the bias high. In this case, the subject will be quite confident about some wrong knowledge after a few initial steps. Thus, more steps are needed to correct it. To prevent this case, instead of minimizing the expected risk, we try to minimize the expected bias while keeping the variance untouched. Replacing \( R(p_t) \) in Eq. 20 by the bias term \( (\mu_t - \theta^*)^2 \), we have the new optimization problem,

\[ \lambda_t = \arg \min_{\lambda \in [0,1]} E_{\psi_t}(\lambda) \left[ (\mu_t - \theta^*)^2 \right]. \]  

(21)

V. Simulation

In our simulation, all angles are confined in \((-\pi, \pi]\). Thus, the distribution of the subject's knowledge \( p_t(\theta) \) is the wrapped Gaussian distribution, \( p_t(\theta) = \sum_{j \in Z} q_t(\theta + 2j\pi), \) where \( q_t(x) = N(\mu_t, \sigma_t^2). \) And the distance between two angles \( \theta \) and \( \theta^* \) is defined as \( \min_{j \in Z} |\theta - \theta^* + 2j\pi|^2. \)

At the beginning, the subject's knowledge \( p_0 \) is a uniform distribution on \((-\pi, \pi]. \) It is equivalent to the wrapped Gaussian distribution with infinity variance and in the first updating the subject will fully trust the likelihood.

The home position is \((0, 0)\) and the target is randomly posed on a circle with radius 50. The cursor's step length is 1. We repeat 100 times of the learning process and each time the system parameter \( \theta^* \) is uniformly sampled from \((-\pi, \pi]. \)

The results shown are averaged over those 100 trials.

The learning curves of risk defined in Eq. 19 corresponding to different difficulty control strategies are compared. We also compare the subject's actual error, which is the difference between the subject's intended output and the desired direction, i.e., \( L_t = \left( f(\varphi_t; \theta^*) - \psi_t \right)^2. \) Since the results of \( L_t \) are similar to those of risk, we do not show the comparison here.

A. Results

In the first simulation experiment, we fix the task difficulty \( \lambda \) throughout the whole process to study the properties of the proposed learning framework. The results are shown in Fig. 2. Here we consider three values of \( \alpha, \) small one \((\alpha = e^0), \) median one \((\alpha = e^2), \) large one \((\alpha = e^4)\) and three values of \( \lambda, \) easy one \((\lambda = 0.2), \) median one
(λ = 0.6), hard one (λ = 1). As we have seen in Sec. III-B, when α increases, the capability of the subject acquiring new information decreases. Thus α = e^0 corresponds to the case where the subject can acquire the most information. In this case, simply setting λ = 1 will make the subject learn fastest, just as shown in Fig. 2. As α increases, the subject’s capability of acquiring new information decreases and λ = 1 becomes too difficult for the subject. Thus, at the beginning of the learning process, the convergence rate is quite slow. Therefore, if the subject’s capability is not very strong, making the task easy when the subject knows little about the system is more helpful. This result agrees with the intuition and the statement of [1], [2].

To demonstrate the effectiveness of our proposed difficulty control strategy (denoted as ADP-B), we first compare it with the strategy of fixed difficulty (denoted as FIX). The results are shown in Fig. 3. The blue curves correspond to the learning curves under fixed difficulty and the red one corresponds to our adaptive strategy. The averaged λ trajectory under our strategy is also shown in figures as the red dash curves. From the results we can see that our strategy is almost always better than any fixed difficulty scheduling. That demonstrates the adaptive difficulty control is necessary for fast learning and our strategy provides a good choice.

Finally, we compare ADP-B with other two control strategies. The first one (denoted as AVGTRJ) is using the averaged λ trajectory obtained from ADP-B universally. The second one (denoted as ADP-R) is choosing λ to minimize the subject’s expected risk at each time point as discussed in IV. The results are shown in Fig. 4. The blue dash curve corresponds to the averaged λ trajectory under ADP-R and the red dash curve corresponds to the averaged λ trajectory under ADP-B and AVGTRJ. The deficiency of AVGTRJ compared to ADP-B demonstrates there exists no universal difficulty scheduling that can work well on all trials and the optimal control strategy should be adaptive on different trials.

Just as the discussion in Section IV, ADP-R performs much worse than ADP-B from the results. We find that ADP-R initially decreases quickly, but converges relatively slowly. From Section IV we know this is because ADP-R focuses on reducing the variance of the first several steps. ADP-B, as a greedy heuristic to avoid this problem, results in fairly fast reductions in overall risk, while still allowing rapid convergence of risk to optimal levels.

VI. CONCLUSIONS
The Bayesian learning framework developed here has two novel features that capture the specifics of learning in a
