Abstract

Data-driven approaches for learning dynamic models for Bayesian filtering often try to maximize the data likelihood given parametric forms for the transition and observation models. However, this objective is usually nonconvex in the parametrization and can only be locally optimized. Furthermore, learning algorithms typically do not provide performance guarantees on the desired Bayesian filtering task. In this work, we propose using inference machines to directly optimize the filtering performance. Our procedure is capable of learning partially-observable systems when the state space is either unknown or known in advance. To accomplish this, we adapt PREDICTIVE STATE INFERENCE MACHINES (PSIMs) by introducing the concept of hints, which incorporate prior knowledge of the state space to accompany the predictive state representation. This allows PSIM to be applied to the larger class of filtering problems which require prediction of a specific parameter or partial component of state. Our PSIM+HINTS adaptation enjoys theoretical advantages similar to the original PSIM algorithm, and we showcase its performance on a variety of robotics filtering problems.

1 Introduction

Bayesian filtering plays a vital role in applications ranging from robotic state estimation to visual tracking in images to real-time natural language processing. Filtering allows the system to reason about the current state given a sequence of observations. The traditional filtering setup utilizes a process and sensor model to progress the filter over time (Fig. 1a). The process (dynamics) model describes the transition of the system from state $s_t$ to state $s_{t+1}$ by specifying $P(s_{t+1}|s_t)$, and the sensor (observation) model generates a distribution over observations $P(x_t|s_t)$ given state. Using these models in conjunction with a new observation $x_t$, the filter conditions on observations to compute the posterior $P(s_t|x_t)$. As a result, the performance of the filter, its ability to estimate the state or predict future observations, is limited by the fidelity of dynamics and observation models [Aguirre et al., 2005].

In many domains, such as robotics, it becomes difficult to robustly characterize the dynamics and sensor (observation) physics \textit{a priori} with simple analytic models. As a result, data driven approaches provide an important tool: they allow models of noisy, complicated dynamics to be learned directly from a robot’s interaction with its environment. Learned models can be used for filtering, e.g., the Kalman Filter for linear dynamics and observation models with additive Gaussian noise [Roweis and Ghahramani, 1999], the Unscented Kalman Filter for nonlinear models with Gaussian noise [Van Der Merwe, 2000], or particle filters for nonlinear models from other distributions [Thrun et al., 2005]. The benefits and limitations of each of these approaches is well-known. For example, although the particle filter is capable of representing complex distributions, it has trouble scaling with the dimensionality of the state space. Additionally, errors in the dynamics, sensor, and noise models can compound. The cascading of modeling errors during the predict and update steps can result in poor filtering performance.
Likelihood maximization is the natural optimization target for the filtering problem: we wish to determine the most likely sequence of states from a sequence of observations, often on the graphical model structure of a Hidden Markov Model (Fig. 4). Traditional Maximum Likelihood methods attempt to maximize the likelihood of the observations with respect to a specific parametrization describing the graphical model. However, optimizing for the dynamics’ model parameters is generally a nonconvex objective due to the cascading structure of time series problems [Abbeel and Ng, 2005]. In this work, we introduce an approach that jointly couples both the process and sensor models by directly optimizing for a filter function that predicts the next belief (Fig. 1b).

We learn the filter function by leveraging ideas from inference machines [Langford et al., 2009; Bagnell et al., 2010; Ross et al., 2011b]. An inference machine is a supervised learning approach developed for learning message passing procedures in probabilistic graphical models. Instead of separating the inference problem (e.g. filtering) from the model learning, inference machines directly reduce the problem of learning graphical models to solving a set of supervised learning problems. We specialize inference machines for two settings: the supervised-state setting and the latent-state setting.

In the supervised-state setting, we wish to learn a filter model for a system with a known state representation for which we are able to obtain ground truth at training time. For example, filtering for a simple pendulum (mass on string) dynamical system in this formulation may use a sufficient-state representation of the angle and velocity (θ, ˙θ) with observations of the pendulum’s Cartesian x position. Note that at test time, we do not assume access to the state values and instead infer them by filtering on observations.

The supervised-state setting contrasts with the latent-state setting in that the sufficient underlying state representation is at least partially unobserved at training time. In the pendulum example, if the system state is parametrized by only θ, then the representation would be insufficient to predict future states and observations. This partial-parametrization may be a result of any inability to collect training data of the full state at training time or we may not know the full representation of the underlying state. To address this setting, we extend Predictive State Inference Machines (PSIMs) [Sun et al., 2015] to exploit any partial-parametrization or side-information of state, which we denote as “Hints” about the state.

Concretely, the original PSIMs address prediction over the space of future observations. Many real world applications, however, require the estimation or prediction of useful physical quantities, which traditional filtering algorithms are capable of but PSIMs were not. Our extension, PSIM+Hints, adds this vital capability, allowing PSIMs to be used in a wide range of filtering application domains including neural signal decoding for prosthetic control, visual tracking where a bounding-box must be predicted, and robot localization. The estimated physical quantities in each domain are the Hints we aim to predict in our framework.

In contrast with the learning literature for system identification, which focuses on learning state representations and corresponding transition and observation models, this work focuses on the filtering or inference task where the observer is maintaining a belief about the current state of the system. We present Predictive State Inference Machines with Hints (PSIM+Hints) to directly target the inference task of filtering on latent-state space models. As a special case of PSIM+Hints, we develop the Inference Machine Filter (IMF) for the supervised-state graphical model. Both procedures learn a filter function that uses the current belief state and latest observation to predict the next belief state. The algorithms that we present for learning these inference machines are easy to implement, data-efficient, make no assumptions on the differentiability of the underlying learners, and give theoretical guarantees on the inference task.

2 Inference Machines for Latent-State Models

First, we consider the latent-state setting and introduce Predictive State Inference Machines (PSIMs). We then describe and analyze our novel addition to this underlying framework, which we call Predictive State Inference Machine with Hints (PSIM+Hints). This allows us to consider a partially-observed state setting and use inference machines for filtering. We then show that PSIM+Hints can be easily adapted to learn Inference Machine Filters (IMFs) for the supervised-state setting in Section 3.
2.1 Predictive State Inference Machines

The inference machine approach of [Ross et al., 2011b] cannot be applied to learning latent-state space models since we do not have access to the hidden states’ information at training time (versus the supervised-state setting). This difficulty can be overcome by leveraging ideas from Predictive State Representations (PSRs) [Littman et al., 2001; Singh et al., 2004; Boots et al., 2011; Hefny et al., 2015]. In contrast to latent variable representations like HMMs [Siddiqui et al., 2010; Hsu et al., 2012; Song et al., 2010] or linear state models [Van Overschee and De Moor, 2012], which represent the belief state as a distribution over the latent-state space of the model, PSRs instead maintain an equivalent belief over sufficient features of future observations. Specifically, we assume that there exists a bijective function such that:

\[ m_t = P(s_t|p_t) \Leftrightarrow P(f_t|p_t), \]

where \( f_t = [x_{t+k}, \ldots, x_{t+1}] \) is the sequence of future observations and \( p_t = [x_t, \ldots, x_0] \) is the full history of past observations. We further assume that there exists a bijection \( P(f_t|p_t) \) to the conditional expectation \( E[\phi(f_t)|p_t] \) for feature function \( \phi \). For example under a Gaussian distribution \( E[\phi(f_t)|p_t] = E[f, f^T|p_t] \), the sufficient statistics for the distribution.

With this representation, the PREDICTIVE STATE INFERENCE MACHINE (PSIM) [Sun et al., 2015] uses the predictive state for supervised training in the inference machine framework. More formally, the goal is to learn an operator \( F \) that can deterministically pass the predictive states forward in time conditioned on the latest observation,

\[ E[\phi(f_{t+1})|p_{t+1}] = F(E[\phi(f_t)|p_t], x_t), \]

such that the likelihood of the observations \( \{f_t\}_t \) generated from the sequence of predictive states \( \{E[\phi(f_t)|p_t]\}_t \) is maximized. As this is a sequential prediction problem over the predictive states, DAGger [Ross et al., 2011a] is used to optimize the inference machine. The choice of learner for \( F \) can be any no-regret regression or classification algorithm.

2.2 Predictive State Inference Machine with Hints

In this section, we extend PSIMs to models with partially observable states or side-information (Fig. 3a). This structure shows up in many practical problems. The “Hints” \( h \) may be a bounding-box in visual tracking, the decoded command from a brain-computer interface, or the pose of a robot. In this semi-supervised setup, the hints \( h \) and observations \( x \) are at training time though the true sufficient-state \( s \) is either unknown or unobserved. Although PSIM is well defined on a simple chain-structured model (e.g., Fig. 4), it is not straightforward to extend PSIM to a model with the complicated latent structure in Fig. 3a.

To handle this type of graph structure, we collapse the hints \( h \) and the latent states \( s \) into a single unit-configuration as shown in the abstracted factor graph, Fig. 3b, and only focus on the net message passed into the configuration and the net message passed out from the configuration. Ideally, we would like to design an inference machine that mimics this net message passing procedure.

![Figure 3: (a): Adding hints, \( h_t \), allow us to extend the HMM model with partially observed states (labels). The true latent-states \( s_t \) of an unknown representation generate observations \( x_t \) and labels \( h_t \) of which both are observed at training time but only the former at inference time. The state \( s_t \) and hint \( h_t \) together generate the next label \( h_{t+1} \). (b): If we do not need the messages passed between the states and hints, we can abstract them away and consider the net message output by the hint and state before the process model, drawn as the black square factor, but after the observation update.](image)
We are then capable of training an inference machine that mimics the following predictive state flow:

$$m_t = F(m_{t-1}, x_t),$$

which takes the previous predictive state $m_{t-1}$ and current observation $x_t$ and outputs the next predictive state $m_t$.

Define $\tau \sim D$ as a trajectory $\{x_1, h_1, \ldots, x_T, h_T\}$ of observations and hints sampled from an unknown distribution $D$. Given a function $F \in \mathcal{F}$, let us define $\hat{m}_\tau^{\tau}$ as the corresponding predictive state generated by $F$ when rolling out using the observations in $\tau$ described in Eq. 6.

Similar to PSIM, we aim to find a good hypothesis $F$ from hypothesis class $\mathcal{F}$, that can approximate the true messages well. Hence, we define the following objective function:

$$\min_{F \in \mathcal{F}} \frac{1}{T} \mathbb{E}_{\tau \sim D} \left[ \sum_{t=1}^{T} d(F(\hat{m}_{t-1}, x_t), (h^*_t, x_{t+1:T+k})) \right],$$

s.t., $\hat{m}_t = F(\hat{m}_{t-1}, x_t), \forall t,$

(7)

where $d$ is the loss function that measures how good the predictive states are (e.g., the likelihood of $(h^*_t, x_{t+1:T+k})$ being generated from $\hat{m}_t^{\tau}$ or the squared loss).

The optimization objective presented in Eq. 7 is generally nonconvex in $F$ due to the objective involving sequential prediction terms where the output of $F$ from time-step $t-1$ is used as the input in the loss for the next timestep $t$. Often, a simpler surrogate objective function is considered that only optimizes over single-step predictions. However, optimizing the one-step error alone can result in cascading errors of $O(\exp(T))$ [Venkatraman et al., 2015]. As optimizing Eq. 7 directly is impractical, we utilize Dataset Aggregation (DAgger) [Ross et al., 2011a] to find a filter function (model) $F$ with bounded error. The training procedure for PSIM+HINTS is detailed in Algorithm 1. By rolling out the learned filter and collecting new training points (lines 6, 7), subsequent models are trained (line 9) to be robust to the induced message distribution caused by sequential prediction.

Specifically, let us define $z^*_t = (h^*_t, x_{t+1:T+k})$ for any trajectory $\tau$ at time step $t$ and define $d_F$ as the joint distribution of $(\hat{m}_{t-1}^F, x_t^F, z_t^F), \forall t$ when rolling out $F$ on trajectory $\tau$ sampled from $D$. Then our objective function can be represented alternatively as $\mathbb{E}_{(m,x,z) \sim d_F} d(F(m, x), z)$. Alg. 1 guarantees to output a hypothesis $\hat{F}$ such that:

$$\mathbb{E}_{\tau \sim D} \frac{1}{T} \sum_{t=1}^{T} d(F(\hat{m}_{t-1}^\tau, x_t^\tau), z_t^\tau) \leq \epsilon,$$

(8)

where

$$\epsilon = \min_{F \in \mathcal{F}} \frac{1}{N} \sum_{n=1}^{N} \mathbb{E}_{(m,x,z) \sim d_{F_n}} d(F(m, x), z),$$

(9)

which is the minimum batch minimization error from the entire aggregated dataset in hindsight after $N$ iterations of Alg. 1. This result follows by a reduction to DAgger optimization [Ross et al., 2011a] (similar to that in [Venkatraman et al., 2015; Sun et al., 2015]). Note that this bound applies to Eq. 7 for the $F$ found by Alg. 1. Despite the learner’s loss $\epsilon$ in Eq. 9 being over the aggregated dataset, it can be driven low (e.g. with a powerful learner), making the bound useful in practice. For long-horizons, the possible exponential rollout error from optimizing only the one-step error dominates the error over the aggregated dataset.

We conclude with a few final notes. First, even though $F_0$ would ideally be initialized (line 3) by optimizing for the transition between the true messages, in practice $F_0$ is often initialized from the empirical estimates. Second, though the sufficient-feature assumption is common in the PSR literature [Hefny et al., 2015], an approximate feature transform $\phi$ balances computational complexity with prediction accuracy: simple feature design (e.g., first moment) makes for faster training of $F$ while Hilbert Space embeddings are harder to optimize but may improve accuracy [Boots, 2012; Boots et al., 2013]. Additionally, the bound in Eqs. 8, 9 holds for the approximate message statistics. Finally, though the learning procedure is shown in a follow-the-leader fashion on the batch data (line 9), we can use any online no-regret learning algorithm (e.g. OGD [Zinkevich, 2003]), alleviating computational and memory concerns.

**Hint Pre-image Computation**

Since the ultimate goal is to predict the hint, we need an extra step to extract the information of $h_t$ from the computed predictive state $\hat{m}_t$, which is an approximation of the true conditional distribution $P(h_t, x_{t+1:T+k} | \tau_0)$. Exactly computing the MLE or mean of $h_t$ from $\hat{m}_t$ might be difficult (e.g., sampling points from a Hilbert space embedding is not trivial [Chen et al., 2012]). Instead, we formulate the step of extracting $h_t$ from $\hat{m}_t$ as an additional regression step:

$$\min_{g \in \mathcal{G}} \mathbb{E}_{\tau \sim D} \frac{1}{T} \sum_{t=1}^{T} ||g(\hat{m}_t^\tau) - h_t^\tau||^2$$

(10)

To find $g$, we roll out $\hat{F}$ on each trajectory from the training data and collect all the pairs of $\hat{m}_t^\tau, h_t^\tau$. Then we can use any powerful learning algorithm to learn this pre-image mapping.
g (e.g., random forests, kernel regression). Note that this is a standard supervised learning problem and not a sequential prediction problem — the output from g is not used for future predictions using g or the filter function \( \hat{F} \).

3 The INFEERENCE MACHINE Filter for Supervised-State Models

In contrast to filter learning in the latent-state problem, the supervised-state setting affords us access to both the sufficient-state \( s \) and observations \( x \) during training time. We specifically look at learning a filter function on Hidden Markov Models (HMMs) as shown in Fig. 4. This problem setting similar to those considered in the learning-based system identification literature (e.g. [Ko and Fox, 2009; Nishiyama et al., 2016]). However, these previous methods use supervised learning to learn independent dynamics and observation models and then use these learned models for inference. This approach may result in unstable dynamics models and poor performance when used for filtering and cascading prediction. Instead, we directly optimize filtering performance by adapting PSIM+HINTS to learn message passing in this supervised setting. We term this simpler algorithm as the INFEERENCE MACHINE Filter (IMF).

Referencing Algorithm 1, the IMF simply sets the hints \( h_t \) in PSIM+HINTS to be the observed states \( s_t \) and sets the number of future observations \( k_f = 0 \); in other words, \( s_t \) is assumed to be a sufficient-state representation. The IMF learns a deterministic filter function \( F \) that combines the predict-and-update steps of a Bayesian filter to recursively compute:

\[
P(s_t|p_t) \Leftrightarrow \mathbb{E}[\phi(s_t)|p_t] = m_t = F(m_{t-1}, x_t)
\]

The INFEERENCE MACHINE FILTER (IMF) can be viewed as a specialization of both the theory and application of inference machines to the domain of time-series hidden Markov models. Our guarantee in Eq. 8 shows that the prediction error on the messages optimized by Dagger is bounded linearly in the filtering problem’s time horizon. Additionally, the sufficient feature representation of PSIM+HINTS allows IMFs to represent distributions over continuous variables, compared to the discrete tabular setting of [Ross et al., 2011b].

The IMF approach differs from [Langford et al., 2009] in several important ways. Langford et al. learn four operators: one to map the first observation to initial state, one for the belief update with an observation, one for state-to-state transition, and one for state to observation. This results in a more complex learning procedure as well as a special initialization procedure at test time for the filter. Our algorithm only learns a single filter function instead of four. It also operates like a traditional filter; it is initialized from a prior over belief state instead of mapping from the first observation to the first state. Finally, Alg. 1 does not assume differentiability of the learning procedure as required for the backpropagation-through-time learning used in [Langford et al., 2009].

4 Experiments

We focus on robotics-inspired filtering experiments. In the supervised-state representation, we are given the state (e.g. robot’s pose) and observations (e.g. IMU readings) at training time. In the latent-state setting, we only gain access to the observations and instead of observing the full state at training time, we see only a hint (e.g. only the \( x \)-position of the pose). In both scenarios, the hint or state could be collected by instrumenting the system at training time (e.g. having the robot in a motion capture arena), which we then do not have access to at test time (e.g. robot moves in an outdoor area).

The latent-state setting with hints is additionally relevant in domains where it is difficult to observe the full state but easy to observe quantities that are heavily correlated with it.

4.1 Baselines

We compare our approach against both learning-based algorithms as well as physics based, hand-tuned filters when relevant. For the first baseline, we compare against a learned linear Kalman filter (Linear KF). Here, the hints \( h \) are the states \( X \) for the Kalman filter and \( Y \) are the observations. We learn the Kalman filter using the MAP estimate:

\[
A = \arg \min_A \| AX_t - X_{t+1} \|^2_2 + \beta_1 \| A \|^2_F
\]

\[
C = \arg \min_C \| CX_t - Y_t \|^2_2 + \beta_2 \| C \|^2_F
\]

\[
Q = \text{cov}(AX_t - X_{t+1}), R = \text{cov}(CX_t - Y_t)
\]

We select the regularization (Gaussian prior) terms \( \beta_1, \beta_2 \) by cross-validation.

We also compare against a model that uses a fixed-sized history \( k_p \) of observations to predict the hint at the next time step. We find this model by optimizing the objective,

\[
AR = \arg \min_{AR} \sum_{t=k_p}^{T-1} \| AR[\{y_{t-k_p}, \ldots, y_t\}] - h_t \|^2_2,
\]

where \( h_t \) is the hint we wish to predict at timestep \( t \), \( y_{t-k_p}, \ldots, y_t \) are past observations, and \( AR \) is the learned function. This baseline is similar to Autoregressive (AR) Models [Wei, 1994]. It is important to note that using a past sequence of observations is different than tracking a belief over the future observations (the predictive state) as PSIM does. The AR model does not marginalize over the whole history as a Bayesian filter would. In our experiments, we set the history (past) length \( k_p = 5 \). Choosing higher \( k_p \) reduces the comparability of the results as the AR model has to wait \( k_p \) timesteps before giving a prediction while the other filter
algorithms predict from the first timestep. To get good performance, we chose the AR model to be Random Fourier Features (RFF) regression [Rahimi and Recht, 2007] with hyperparameters tuned via cross-validation.

Finally, on several of the applicable dynamics benchmarks below, we also compare against a hand-tuned filter for the problem. The overall error is reported as the mean L2 norm error \( \frac{1}{T} \sum_{t=1}^{T} ||h_t - \hat{h}_t||^2 \).

### 4.2 Dynamical Systems

We describe the experimental setup below for each of the dynamical system benchmarks we use. A simulated pendulum is used to show that the inference machine is competitive with, and even outperforms, a physics-knowledgeable baseline on a sufficient-state representation. This simulated dataset additionally illustrates the power of using predictive state when we only access a partial-state to use as a hint. Two real-world datasets show the applicability of our algorithms on robotic tasks. The numerical results are computed across a k-fold validation (\( k = 10 \)) over the trajectories in each dataset. We use linear regression or Random Fourier Feature (RFF) regression to learn the message passing function \( F \) for PSIM+HINTS and IMF and report the better performing result. Random forests [Breiman, 2001] or RFF regression are used to learn the pre-image map \( g \), chosen by cross-validation over that k-fold’s training trajectories.

#### Pendulum State Estimation

In this problem, the goal is to estimate the sufficient state \( s_t = h_t \equiv (\theta, \dot{\theta})_t \) from observations \( x_t \) of the Cartesian coordinate of the mass at the end of pendulum. For PSIM+HINTS and IMF we use a message that approximates the first two moments. This is accomplished by stacking the state with its element-wise squared value, with the latter approximating the covariance by its diagonal elements. IMF does this for only the state while PSIM+HINTS does this for the hint (state) and the future observations. Since we know the dynamics and observation models explicitly for this dynamical system, we also compare against a baseline that can exploit this domain knowledge, the Unscented Kalman Filter (Physics UKF) [Wan and Van Der Merwe, 2000]. The process and sensor models given to the UKF were the exact functions used to generate the training and test trajectories.

#### Quadrotor Attitude Estimation

To illustrate the utility of tracking a predictive state, consider the same simulated pendulum where we take the partial state, \( \theta_t \) as the hint \( h_t \) for PSIM+HINTS and use as the (insufficient) state \( s_t \) for the IMF. We use the first and approximate second moment features to generate the messages. On this benchmark, we do not compare against a UKF physics-model since the partial state is not sufficient to define a full process model of the system’s evolution.

Table 3: Performance on mass estimation task

Mass Estimation from Robot Manipulator

This dataset tests the filter performance at a parameter estimation task where the goal is to estimate the mass carried by the robot manipulator shown in Fig. 2b. Each trajectory has the robot arm lift an object with mass 45g-355g. The robot starts moving at approximately the halfway point of the recorded trajectories. We use as observations the joint angles and joint motor torques of the manipulator. Only first moment features are used for the messages for PSIM+HINTS. With this experiment, we show that that filtering helps reduce error compared to using simply a sequence of past observations (AR baseline) even on a problem of estimating a parameter held static per test trajectory.

5 Discussion & Conclusion

In all of the experiments, IMF and PSIM+HINTS outperform the baselines. Table 1 (left column) shows that the IMF and PSIM+HINTS both outperform the baseline Unscented Kalman Filter which uses knowledge of the underlying physics and noise models. We do not compare against a learned-model UKF, such as the Gaussian Process-UKF [Ko and Fox, 2009], because any learned dynamics and observation models would be less accurate than the exact ones in our Physics UKF baseline. For fair comparison, the UKF, Linear KF, IMF, and PSIM+HINTS all start with empirical estimates of the initial belief state (note the similar error at the beginning of Fig. 5a). We believe that the IMF and PSIM+HINTS outperforms the Physics UKF for two reasons: (1) Inference machines do not make Gaussian assumptions on the belief updates as the UKF does, (2) The large variance for the UKF (Table 1) shows that it performs well on some trajectories. We qualitatively observed this variance is heavily correlated with the difference between the UKFs initial belief-state evolution and the true states. Our proposed inference machine filter methods instead directly optimize the filter’s performance over all of the time-horizon are are thus more robust to the initialization of the filter.

The simulated pendulum example also demonstrates the usefulness of predictive representations. When a sufficient state is used (i.e. $(\theta, \dot{\theta})$ for the pendulum) for the filter’s belief, similar performance is achieved using either IMF or PSIM+HINTS. Table 1’s right column (or Fig. 5b) shows that when a partial-state representation is used instead (i.e. $(\theta)$), PSIM+HINTS vastly outperforms IMF. Specifically, we require a larger predictive state representation (larger $k_f$) over the observation space in order to better capture the evolution of the system. This ablation-style experiment demonstrates the ability of PSIM+HINTS to produce more accurate filters.

Finally, our real-world dataset experiments provide additional experimental validation of inference machines for filtering. Both the IMF and PSIM+HINTS outperform baselines in Table 2. In Fig. 5d, PSIM+HINTS is on average 50% more accurate at the end of the trajectory than the AR baseline; the average error over the whole trajectory is given in Table 3. For this problem, the largest information gain is when the robot starts moving halfway along the trajectory. We see less performance gain from using a filter compared to the AR baseline in this problem as the hint (mass) does not change over time as the state does in pendulum or quadrotor problems. The the error versus time plots in Fig. 5 show the relative stability of the inference machine filters even over large time horizons.

In this work, we presented a novel class of inference machines, PSIM+HINTS, which can leverage powerful discriminative supervised learning algorithms to directly approximate belief propagation for filtering on time-series and dynamical systems. The proposed algorithms show promise in many robotic applications where ground-truth information about state is available during training, for example by overinstrumenting to get the hints or state values during prototyping or calibration. We empirically validated our approaches on several simulated and real world tasks, illustrating the advantage of PSIMs+HINTS and IMFs over previous methods.
