This report is to appear in Analytic Computational Complexity
Complexity is a measure of cost. The relevant costs depend on the model under analysis. The costs may be taken as units of time (in parallel computation), number of comparisons (in sorting algorithms), size of storage (in large linear systems), or number of arithmetics (in matrix multiplication). Of course a number of different costs may be relevant to a model. One can analyze the complexity of an algorithm, of a class of algorithms, or of a problem. The subject dealing with the complexity of an algorithm is usually called "Analysis of Algorithms". The subject dealing with the analysis of a class of algorithms or of a problem is called computational complexity.

Computational complexity comes in many flavors depending on the class of algorithms, the problem, and the costs. We limit ourselves here to mentioning three types of computational complexity. In each of these the costs are taken as the arithmetic operations. Algebraic computational complexity deals with a problem and a class of algorithms which solve the problems at finite cost. Typically the problem belongs to a class of problems which is indexed by an integer $n$. Let
Let $\text{comp}(P_n)$ be the complexity of solving the $n$th problem in the class. We are interested in lower bounds $L(P_n)$ and upper bounds $U(P_n)$ on $\text{comp}(P_n)$,

$$L(P_n) \leq \text{comp}(P_n) \leq U(P_n).$$

The upper bounds are obtained by exhibiting an algorithm for solving $P_n$ with complexity $U(P_n)$. Lower bounds are obtained by theoretical considerations and "non-trivial" lower bounds are difficult to obtain. For example if $P_n$ is the problem of multiplying two $n$ by $n$ matrices and if the cost of each arithmetic operation is taken as unity then

$$O(n^2) \leq \text{comp}(P_n) \leq O(n^p), \quad p = \log_2 7.$$  

(We use $\log$ to represent $\log_2$.) 

Borodin and Munro [75] survey the state of knowledge in algebraic complexity.

Exact solutions of "most" problems in science, engineering, and applied mathematics cannot be obtained with finite cost even if infinite-precision arithmetic is assumed. Indeed linear problems and evaluation of rational functions which can be solved at finite cost are the exception. Even when the problem can be solved rationally, we may choose to solve it by iteration. An example is the solution of large sparse linear systems. Typically, non-linear problems cannot be solved at finite cost.

We call the branch of complexity theory that deals with non-finite cost problems analytic computational complexity. Often the algorithms are iterative and we then refer to iterative computational complexity.

In this paper we propose a new methodology for iterative computational complexity. Our aim is to create at least a
partial synthesis between iterative complexity and other types of complexity.

A basic quantity in iterative complexity has been the efficiency index of an algorithm or class of algorithms. In this paper we introduce a new quantity, the complexity index, which is the reciprocal of the efficiency index. The complexity index is directly proportional to the complexity of an algorithm or class of algorithms. We show under what conditions the complexity index is a good measure of complexity. Our methodology is non-asymptotic in the number of iterations. Earlier analyses of complexity applied only as the number of iterations went to infinity and this is not of course realistic in practice.

We summarize the contents of this paper. In Section 2 we analyze a simplified model of the errors of an iterative process and show that complexity is the product of two factors, the complexity index and the error coefficient function. Bounds on the error coefficient function are derived in the following Section and used to derive rigorous conditions for comparing the complexity of two different algorithms. In Section 4 we show how the results of the simple model can be applied to a realistic model of one-point iteration. Lower and upper bounds on the complexity index for several important classes of iterations appear in Section 5. In a short concluding Section we state the extensions and generalizations to be reported in future papers.

2. BASIC CONCEPTS

We analyze algorithms for the following problem. Let $f$ be a non-linear real or complex scalar function with a simple zero $\alpha$. Let $x_0$ be given and let an algorithm $\phi$ generate a
sequence of approximations $x_1, \ldots, x_k$ to $\alpha$. We terminate the algorithm when $x_k$ is a sufficiently good approximation to $\alpha$. This will be made precise below.

The appropriate setting for this investigation is to consider $f$ as a non-linear operator on a Banach space of finite or infinite dimension. Since many of the basic ideas can be illustrated when $f$ is a non-linear scalar function we shall assume throughout this paper that this holds. We must remark however that some of the most interesting and important results deal with the dependence of complexity on problem dimension and we do not deal with that dependence here.

Let $e_i > 0$ represent some measure of the error of $x_i$. For example, $e_i$ might represent

\[
\begin{align*}
| x_i - \alpha |, & \text{ the absolute error} \\
\frac{| x_i - \alpha |}{| \alpha |}, & \text{ the relative error} \\
| f(x_i) |, & \text{ the residual}.
\end{align*}
\]

Assume that the $e_i$ satisfy the error equation

\begin{equation}
(2.1) \quad e_i = A_i e_{i-1}^p, \quad p \geq 1, \quad i = 1, 2, \ldots, k.
\end{equation}

We call $p$ the non-asymptotic order and $A_i$ the error coefficient. We require $0 < L \leq A_i \leq U < \infty$ for all values of $e_0$ including the possibility that $e_0$ be arbitrarily small. Then $p$ is unique. Many iterations satisfy the model given by (2.1). In Section 6 we mention extensions to this model.

EXAMPLE 2.1. Let the algorithm be Newton-Raphson iteration and let $e_i$ denote the absolute error. Then
where $T_i$ is in the interval spanned by $x$ and $x_i$.

We simplify the model of (2.1) and show what kind of results may then be obtained. In Section 4 we return to the analysis of (2.1). Let

\[(2.2) \quad e_i = A e_{i-1}^p, \quad p > 1, \quad i = 1, \ldots, k.\]

We call this the constant error coefficient model while (2.1) is the variable error coefficient model.

We consider first the case $p > 1$. It is easy to verify that

\[(2.3) \quad e_i = e_0 \left(\frac{1}{w_p}\right)^{i-1}, \quad i = 0, \ldots, k,\]

where

\[(2.4) \quad w_p = \frac{1}{A^{p-1} e_0}.\]

Choose $\epsilon'$, $0 < \epsilon' < 1$, and let $k$ be the smallest index for which $e_k \leq \epsilon' e_0$. Define $\epsilon \leq \epsilon'$ so that

\[(2.5) \quad e_k = \epsilon e_0.\]

$\epsilon'$ is a basic parameter which measures the increase in precision to be obtained in the iteration. We choose $\epsilon$ to avoid ceiling and floor functions later in this paper. It is convenient to assume $\epsilon \leq 2^{-2}$ (we use this in Theorem 3.1) but this is non-restrictive in practice.

From (2.3), (2.5),
and it follows that

\[(2.7) \quad k = \frac{g(w_p)}{\lg p},\]

where

\[(2.8) \quad g(w_p) = \lg \left(1 + \frac{t}{\lg w_p}\right), \quad t = \lg \left(\frac{1}{\epsilon}\right).\]

This is independent of the logarithm base but it is convenient to take all logarithms to base 2. Then, if \(e_i\) is the relative error, \(t\) measures the number of bits to be gained in the iteration.

We denote the complexity of iteration \(i\) by \(c_i\). In this paper we assume \(c_i = c\) is independent of \(i\). We defer a discussion of the estimation of \(c\) until Section 5. The important case of variable cost will be considered in a future paper. We define the complexity of the algorithm by

\[(2.9) \quad \text{comp} = ck.\]

Then from (2.7), (2.8),

\[(2.10) \quad \text{comp} = zg(w_p)\]

where we define

\[(2.11) \quad z = \frac{c}{\lg p}.\]

as the complexity index.

We call \(g\) the error coefficient function. Equation (2.10) will be fundamental in our further analysis.

We have decomposed complexity into the product of two factors. The complexity index, which is independent of both
the error coefficient and the starting error, is relatively
easy to compute for any given algorithm. (However, lower
bounds on the complexity index for classes of algorithms re­
quire upper bounds on order which is a difficult problem only
solved for special cases (Kung and Traub [73], Meersman [75]
and Woźniakowski [75b]).) We shall show, in a sense to be
made precise in the next section, that the error coefficient
is insensitive for a large portion of its domain and that
complexity is determined primarily by the complexity index.
We shall also show there are cases where complexity is deter­
mined primarily by the error coefficient function.

The complexity index is the reciprocal of a quantity
called the efficiency index which has played an important role
in iterative complexity. See, for example, Traub [64, Appen­
dix C], Traub [72], Paterson [72] and Kung [73a]. Since com­
plexity varies directly with the complexity index we feel that
the complexity index rather than the efficiency index, should
be basic.

We have been considering the case \( p > 1 \). For complete­
ness we write down the case \( p = 1 \). Then \( e_i = A e_{i-1}, i = 1, \\
2, \ldots, k \) and \( e_k = A^k e_0 = e e_0 \). Hence

\[
(2.12) \quad k = \frac{t}{1 \lg \left( \frac{1}{A^r} \right)}, \quad \text{comp} = \frac{-ct}{1 \lg \left( \frac{1}{A^r} \right)}.
\]

We shall not pursue the case \( p = 1 \) further and shall assume
for the remainder of this paper that \( p > 1 \), unless we state
otherwise.

3. BOUNDS ON THE ERROR COEFFICIENT FUNCTION

We turn to an analysis of the error coefficient function
which is one of the two factors which determines the complex­
ity in (2.10). To see which values of \( w_p \) are of interest,
note that from (2.3), $e_k < e_0$ iff $w_p > 1$. From the definition of $k$ it is clear that $k \geq 1$ and hence from (2.7), (2.8),

$$w_p \leq \left(\frac{1}{e}\right)^{p-1}.$$ 

Hence we assume

$$1 < w_p \leq \left(\frac{1}{e}\right)^{p-1} = 2^{p-1}. \tag{3.1}$$

Generally $w_p$ depends on $p$. For many classes of iterations

$$a^{p-1} \leq A \leq b^{p-1}. \tag{3.2}$$

Then

$$\frac{1}{ae_0} \geq w_p \geq \frac{1}{be_0}$$

and the bounds on $w_p$ are independent of $p$. If (3.2) holds for a class of iterations $\xi$ we shall say that $\xi$ is normal.

An example of a normal class of iterations may be found in Wozniakowski [75b]. To simplify notation we shall henceforth write $w_p$ as $w$ whether or not we are dealing with a normal class.

Now, $g(w)$ is a monotonically decreasing function and

$$\lim_{w \to 1^+} g(w) = \infty, \lim_{w \to \infty} g(w) = 0.$$ 

To study the size of $g(w)$ we somewhat arbitrarily divide the range of $w$, given by (3.1), into three sub-ranges.

$1 < w \leq 2$. Since $g(w) = \lg(t + \lg w) - \lg \lg w$ and $0 < \lg w \leq 1$, we conclude

$$\lg t - \lg \lg w < g(w) \leq \lg(1 + t) - \lg \lg w.$$
\[ 2 \leq w \leq t. \] Since \( g(w) \), \( g(2) = \lg(1+t) \), \( g(t) > \lg t - \lg \lg t \), we conclude

\[ \lg t - \lg \lg t < g(w) \leq \lg(1+t). \]

\[ \frac{t}{2^{p-1}}, \frac{t}{2^{p-1}} \geq t. \] Then

\[ \lg p \leq g(w) < 1 + \lg t - \lg \lg t. \]

To get some feel for the length of these sub-ranges, observe that if \( e \) represents relative error then in single-precision computation on a "typical" digital computer we might take \( e = 2^{-32} \). Then \( t = 32 \) and if \( p = 2 \), then \( 2^{p-1} = 2^{32} \).

From the bounds on the error coefficient function and (2.10) we immediately obtain the following bounds on complexity.

**Theorem 3.1.** If \( 1 < w \leq 2 \),

\[ (3.3) \ z(\lg t - \lg \lg w) \leq \text{comp} \leq z(\lg(1+t) - \lg \lg w). \]

If \( 2 \leq w \leq t \),

\[ (3.4) \ z(\lg t - \lg \lg t) \leq \text{comp} \leq z\lg(1+t). \]

If \( t \leq w \leq 2^{p-1} \), (with \( 2^{p-1} \geq t \)),

\[ (3.5) \ c \leq \text{comp} < z(1 + \lg t - \lg \lg t). \]

We discuss some of the implications of this Theorem.

As \( w \) approaches unity, then for \( e \) fixed, \( \text{comp} \sim z\lg \lg w \). In this case the effect of the error coefficient \( A \) and the initial error \( e_0 \) cannot be neglected.
Complexity depends more on the nearness of \( w \) to unity than of \( \epsilon \) to zero. To see this, observe that if \( 2 \leq w \leq t \), 
\[
\text{comp} \sim z \frac{1}{\log t} \sim \text{comp}_1 
\]
while if \( 1 < w < 2 \), 
\[
\text{comp} \sim z \left( \frac{1}{\log (1/\epsilon)} - \frac{1}{\log w} \right) \sim \text{comp}_2. 
\]
Let 
\[
\epsilon = 2^{-2^j}, w-1=2^{-2^j} \ln 2. 
\]
Then \( \text{comp}_1 = jz \), \( \text{comp}_2 \sim z(j+2^j) \).

Note that for any \( p > 1 \) the complexity of an iteration can be greater than if \( p = 1 \) (see (2.12)) provided \( w \) is sufficiently close to unity.

For any \( w \geq 2 \), complexity is bounded from above by \( z \log (1+t) \) and is therefore independent of the error coefficient \( A \) and the initial error \( e_0 \). For \( w \geq 2 \), complexity is insensitive to \( w \) and we need only crude bounds on \( w \).

For \( 2 \leq w \leq t \),
\[
1 - \frac{\log t}{\log t} \leq \frac{\text{comp}}{z \log t} \leq 1 + \frac{\log (1+t^{-1})}{\log t} 
\]
Therefore
\[
1+o(1) \leq \frac{\text{comp}}{z \log t} \leq 1+o(1) 
\]
and we conclude that on the interval \([2,t]\) we have, for \( t \) large, very tight bounds on \text{comp} with
\[
(3.6) \quad \text{comp} \sim z \log \frac{1}{\epsilon}. 
\]
This should be compared with the case \( p = 1 \) (see (2.12)) where \text{comp} varies as \( \log \frac{1}{\epsilon} \).

We have taken \( w = 2 \) as one of our endpoints for convenience but this is of course arbitrary. Any value of \( w \) sufficiently far from unity will do. If \( w = 2^v \) then \( g(w) = \log (1+vt) \).

Then the effect of the nearness of \( w \) to unity and of \( \epsilon \) to zero are equal if \( v = t \), that is if \( w = 2^t \). For this choice of \( w \), 
\[
\text{comp} = z \log (1+t^2) \sim 2z \log t = 2z \log \frac{1}{\epsilon}. 
\]
We have chosen the sub-ranges of \( w \) so that the endpoints are simple. We could also choose values of \( w \) that make the complexity formula simple. If
\[
w = 2^{t/(t^u-1)}, \quad u \geq 1, \text{ then } \text{comp} = u \log_2 \log \frac{1}{\epsilon},
\]
while if
\[
w = 2^{t/(t^v-1)}, \quad v \geq 1, \text{ then } \text{comp} = \frac{1}{v} \log_2 \log \frac{1}{\epsilon}.
\]

We now consider the methodology for comparing two iterations which are governed by the constant error coefficient model (2.2) and decrease the final error by the same \( \epsilon \). Let \( w_1, z_1, \text{comp}_1, i = 1, 2 \) denote the parameters of the two iterations. Then
\[
\frac{\text{comp}_1}{\text{comp}_2} = \frac{(z_1)g(w_1)}{(z_2)g(w_2)}.
\]
Clearly if \( z_1 \leq z_2 \) and \( w_1 \geq w_2 \) then \( \text{comp}_1 \leq \text{comp}_2 \). We obtain bounds on \( \text{comp}_1/\text{comp}_2 \) for sub-ranges of the \( w_i \). Using the bounds on complexity from the previous theorem we obtain

**Theorem 3.2.** If \( 1 < w_1, w_2 \leq 2 \), then
\[
(3.7) \quad \frac{(z_1)\log t - \log t \log w_1}{(z_2)\log (1+t) - \log w_2} < \frac{\text{comp}_1}{\text{comp}_2} < \frac{(z_1)(\log (1+t) - \log w_1)}{(z_2)\log t - \log w_2}.
\]
If \( 1 < w_2 \leq 2 < w_1 \leq t \), then
\[
(3.8) \quad \frac{(z_1)(\log t - \log t \log w)}{(z_2)(\log (1+t) - \log w_2)} < \frac{\text{comp}_1}{\text{comp}_2} < \frac{(z_1)(\log (1+t) - \log w_1)}{(z_2)\log t - \log w_2}.
\]
If $2 \leq w_1, w_2 \leq t$, then

$$(3.9) \left( \frac{z_1}{z_2} \right) \left( \frac{\log(1+t)}{\log(1+t)} \right) < \frac{\text{comp}_1}{\text{comp}_2} < \left( \frac{z_1}{z_2} \right) \left( \frac{\log(1+t)}{\log(1+t)} \right).$$

We discuss some of the implications of this theorem. As $t \to \infty$, $\text{comp}_1/\text{comp}_2 \to z_1/z_2$ for any fixed values of $w_1, w_2$.

The ratio $z_1/z_2$ has been the way that iterations have been compared (see Traub [64, Appendix C] where efficiency indices are used). Theorem 3.2 shows that $z_1/z_2$ can be a very poor measure of $\text{comp}_1/\text{comp}_2$; see for example (3.7).

Finally we observe that inequalities (3.7)-(3.9) can be rewritten to show when $\text{comp}_1 < \text{comp}_2$ or $\text{comp}_2 < \text{comp}_1$. For example, if $2 \leq w_1, w_2 \leq t$,

$$(3.10) \begin{align*} z_1 < z_2 \left( \frac{\log(1+t)}{\log(1+t)} \right), \end{align*}$$

then $\text{comp}_1 < \text{comp}_2$.

4. THE VARIABLE ERROR COEFFICIENT MODEL

We turn to the variable error coefficient model,

$$(4.1) \begin{align*} e_{i+1} = A_i e_i. \end{align*}$$

A complete analysis of this model is beyond the scope of this paper. Here we confine ourselves to the very simple assumption

$$(4.2) \begin{align*} A_L \leq A_i \leq A_U, \quad i = 1, \ldots, k. \end{align*}$$

Let

$$w_L = \frac{1}{1/A_L^{p-1} e_0}, \quad w_U = \frac{1}{1/A_U^{p-1} e_0}.$$
Then

\[(4.3) \quad \zg(w_L) \leq \text{comp} \leq \zg(w_U)\]

Note that \(w_U \leq w_L\) and therefore (4.3) is compatible with \(g\) being a monotonically decreasing function. We can now draw conclusions from the constant coefficient model with \(A\) replaced by \(A_L\) or \(A_U\).

EXAMPLE 4.1. Let \(\alpha\) be a real zero and let \(J\) denote an interval centered at \(\alpha\). Assume \(f'\) does not vanish in \(J\) and let \(x_0 \in J\) and such that

\[e_0 = |x_0 - \alpha| \leq \frac{\min|f'(x)|}{\max|f''(x)|} = \frac{1}{2A_U}\]

Then by Example 2.1, for Newton-Raphson iteration, \(w_U \geq 2\) and \textit{a priori}

\[(4.4) \quad \text{comp} \leq c \lg(1+t)\]

The value of \(c\) is discussed in Section 5. Note that a sufficient condition for convergence is

\[e_0 < \frac{1}{A_U}\]

but with only this condition, complexity could be extremely large.

EXAMPLE 4.2. We seek to calculate \(a^{1/2}\), that is solve

\[f(x) = x^2 - a.\]

Let \(a = 2^m \lambda^2\), \(m\) even, \(\frac{1}{2} \leq \lambda^2 < 2\). Then \(a^{1/2} = 2^{m/2} \lambda^{1/2}\), \(1/2^{1/2} \leq \lambda < 2^{1/2}\). We use Newton-Raphson iteration,
Then \( A_i = 1/(2x_{i-1}) \). If \( x_0 > \lambda \), then
\[
A_L = \frac{1}{2x_0} \leq A_i < \frac{1}{2\lambda} = A_U, \quad i = 1, \ldots, k.
\]

Hence
\[
w_L = \frac{2}{1-\sqrt{x_0}}, \quad w_U = \frac{2\lambda/x_0}{1-\sqrt{x_0}}.
\]

Let \( x_0 = 2^{1/2} \). Then \( w_U \geq 2 \) and \( \text{comp} \leq c \log(1+t) \). To derive a lower bound on complexity one must make an assumption about the closest machine-representable number to \( 2^{1/2} \). We do not pursue that here.

5. BOUNDS ON THE COMPLEXITY INDEX

We have shown that provided \( w \) is not too close to unity, then for fixed \( c \), complexity depends only on the complexity index \( z \). In this section we turn our attention to the complexity index.

Recall that \( z = c/\log p \). We begin our analysis of \( z \) by considering the cost per step, \( c \). We distinguish between two kinds of problems.

We say a problem is explicit if the formula for \( f \) is given explicitly. For example, the calculation of \( a^{1/2} \) by solving \( f = x^2 - a \) is an explicit problem. The complexity of explicit problems has been studied by Paterson [72] and Kung [73a], [73b]. (Paterson and Kung take the efficiency index as basic.) We do not treat explicit problems here.

We say a problem is implicit if all we know about \( f \) are certain functionals of \( f \). Classically the functionals are \( f \).
and its derivatives evaluated at certain points. These functionals may be thought of as black boxes which deliver an output for any input. Kacewicz [75] has shown that integral functionals are of interest. The question of what functionals may be used in the solution of a problem are beyond the scope of this paper. We confine ourselves to implicit problems for the remainder of this paper.

We assume the same set of functionals is used at each step of the iteration. The set of functionals used by an iteration algorithm $\Phi$ is called the information set $\mathfrak{M}$. Wozniakowski [75a] gives many examples of $\mathfrak{M}$. Let the information complexity $u = u(f, \mathfrak{M})$ be the cost of evaluating functionals on the information set $\mathfrak{M}$ and let the combinatory complexity $d = d(\Phi)$ be the cost of combining functionals (see Kung and Traub [74b]). We assume that each arithmetic operation costs unity and denote the number of operations for one evaluation of $f^{(j)}$ by $c(f^{(j)})$. The following simple example may serve to illustrate the definition.

**EXAMPLE 5.1.** Let $\Phi$ be Newton-Raphson iteration

$$x_{i+1} = \Phi(x_i) = x_i - f(x_i)/f'(x_i), \quad i = 0, \ldots, k-1.$$ 

Then $\mathfrak{M} = \{f(x_i), f'(x_i)\}$, $u(f, \mathfrak{M}) = c(f) + c(f')$, $d(\Phi) = 2$.

Up to this point we have illustrated the concepts with algorithms. Computational complexity deals with classes of algorithms and we turn to our central concern, lower and upper bounds on classes of algorithms. As usual the difficult problem is obtaining lower bounds. Good lower bounds may be obtained from good lower bounds on cost and good upper bounds on order. The problem of maximal order is a difficult one about which a great deal has been recently learned (Meersman [75], Wozniakowski [75a], [75b]). Part of the mathematical
difficulty of the subject deals with the problem of maximal order. Note however that maximal order does not necessarily minimize complexity; we deal with this in a future paper.

Upper bounds are obtained from algorithms. An interesting question here is a good upper bound on the combinatorial complexity of a class of algorithms. Brent and Kung [75] have obtained a surprising new upper bound, $O(n \lg n)$, on the combinatorial complexity on a family of nth order one-point iterations based on inverse interpolation.

It is convenient to index our algorithms by $n$, the number of elements in the information set $\mathfrak{M}$. We illustrate the issues with two examples.

**EXAMPLE 5.2.** Let $\mathfrak{m}_n$ denote any one-point iteration with $\mathfrak{M} = \{f(x_i), f'(x_i), \ldots, f^{(n-1)}(x_i)\}$. Let $\mathfrak{m}_f = \min_i c(f(i))$.

Then $u(f, \mathfrak{m}) \geq n\mathfrak{m}_f$. For simplicity we use the linear lower bound $d(\mathfrak{m}_n) \geq n - 1$. (No non-linear lower bound is known.) A sharp upper bound on the order of one-point iteration (Traub [64], Kung and Traub [74a]) is $p \leq n$. Hence

$$z(\mathfrak{m}_n, f) \geq \frac{n\mathfrak{m}_f n - 1}{\lg n}$$

$$z(\mathfrak{m}_n, f) \geq \frac{n\mathfrak{m}_f n - 1}{\lg n} \geq \frac{3\mathfrak{m}_f}{\lg 3}$$

provided only that $\mathfrak{m}_f \geq 4$ (Kung and Traub [74b]). Hence for any one-point iteration with $w_L \leq t$

(5.1) $\text{comp} \geq \frac{3\mathfrak{m}_f}{\lg 3} (\lg t - \lg \lg t)$.

On the other hand there exists a one-point iteration which uses $f, f', f''$ and such that $p = 3$. Hence if $w_U \geq 2$, 
For problems such that \( c(f) \approx c(f') \approx c(f'') \approx c_f \), the lower and upper bounds of (5.1) and (5.2) are close together.  

**EXAMPLE 5.3.** Kung and Traub [74a] show there exists an iteration \( \psi_n \) for which the information set \( \mathfrak{I} \) consists of \( n \) evaluation of \( f \) with \( p(\psi_n) = 2^{n-1} \) and \( d(\psi_n) = \frac{3}{2^n} + \frac{3}{2^n} - 7 \). Hence

\[
z(\psi_n) = \frac{nc(f)}{n-1} + \frac{3}{2^n} + \frac{3}{2^n} - 7.
\]

The complexity index is minimized (Kung and Traub [74b]) at

\[
n^* = \text{round}\left[ 1 + \left( \frac{2}{3}(c(f)-4)^{1/2} \right) \right] = O(c(f))^{1/2} \text{ and}
\]

\[
z(\psi_{n^*}) = c(f)\left( 1 + \frac{\xi}{(c(f))^{1/2}} \right), \quad \xi > 0.
\]

It would only be reasonable to use this high order iteration for very small \( \epsilon \). Assume \( t > p = 2^{n-1} \).

Observe that \( z(\psi_n) \) is a very "flat" function of \( n \). Thus \( z(\psi_{3/2}) = \frac{3}{2} c(f) + \frac{11}{2} \) and comparing this with \( z(\psi_{n^*}) \) shows we can gain only another \( \frac{1}{2} c(f) \).

Let \( \Psi \) denote the class of all multipoint iterations for which \( \omega_y \geq 2 \). Then

\[
\text{comp}(\Psi) \leq c(f)\lg(1+t)\left( 1 + \frac{\xi}{(c(f))^{1/2}} \right).
\]
of information per step has order \( p \leq 2^{n-1} \). This conjecture seems difficult to prove in general (Woźniakowski [75b]) but has been established for many important cases (Kung and Traub [73], Meersman [75], Woźniakowski [75b]).

6. SUMMARY AND EXTENSIONS TO THE MODEL

We have constructed a non-asymptotic theory of iterative computational complexity with strict lower and upper bounds. In order to make the complexity ideas as accessible as possible we have limited ourselves to scalar non-linear problems. The natural setting for this work is in a Banach space of finite or infinite dimension and we shall do our analysis in this setting in a future paper. We have focussed on the simplified model \( e_i = A e_{i-1}^p \). More realistic models include some of the following features:

1. \( e_i = A_i e_{i-1}^p \) under various assumptions on the structure of \( A_i \).
2. \( e_i = A_i e_{i-1} \cdots e_{i-m}^p \). This is the appropriate model for iterations with memory.
3. Variable cost per iteration, \( c_i \).
4. Include round-off error. Then \( e_i \) will not converge to zero.

We plan to analyze these more realistic models in the future. We also intend to investigate additional basic properties of complexity. Our various results will be used to analyze the complexity of important problems in science and engineering.
ACKNOWLEDGMENT

We thank H. T. Kung for his comments on this paper.
